Financial Contagion

Financial contagion is modeled as an equilibrium phenomenon. Because liquidity preference shocks are imperfectly correlated across regions, banks hold interregional claims on other banks to provide insurance against liquidity preference shocks. When there is no aggregate uncertainty, the first-best allocation of risk sharing can be achieved. However, this arrangement is financially fragile. A small liquidity preference shock in one region can spread by contagion throughout the economy. The possibility of contagion depends strongly on the completeness of the structure of interregional claims. Complete claims structures are shown to be more robust than incomplete structures.

I. Introduction

There is a long tradition of regarding dislocation in the financial sector as a cause of economic fluctuations (Friedman and Schwartz

Earlier versions of this paper were presented in seminars at Boston College, the Federal Reserve Bank of Minneapolis, the International Monetary Fund, Juan Carlos III University, the National Bureau of Economic Research Summer Institute Workshop on Macroeconomic Complementarities, New York University, Pompeu Fabra University, Queen’s University in Kingston, and the University of Pittsburgh. We thank the participants for their helpful comments, especially Russell Cooper, Dean Corbae, Pat Kehoe, Garey Ramey, and Andres Velasco. We are particularly grateful to Lars Hansen (the editor) and an anonymous referee for their suggestions, which have significantly improved the paper. The financial support of the National Science Foundation, the C. V. Starr Center for Applied Economics at New York University, and the Wharton Financial Institutions Center is gratefully acknowledged.
1963; Bernanke 1983; Bernanke and Gertler 1989). According to this view, financial crises are important because they raise the costs of intermediation and restrict credit, which in turn restrain the level of activity in the real sector and ultimately can lead to periods of low growth and recession.

The prevalence of financial crises has led many to conclude that the financial sector is unusually susceptible to shocks. One theory is that small shocks, which initially affect only a few institutions or a particular region of the economy, spread by contagion to the rest of the financial sector and then infect the larger economy. In this paper, we focus on one channel of contagion, the overlapping claims that different regions or sectors of the banking system have on one another. When one region suffers a bank crisis, the other regions suffer a loss because their claims on the troubled region fall in value. If this spillover effect is strong enough, it can cause a crisis in the adjacent regions. In extreme cases, the crisis passes from region to region and becomes a contagion.

In order to focus on the role of one particular channel for financial contagion, we exclude other propagation mechanisms that may be important for a fuller understanding of financial contagion. In particular, we assume that agents have complete information about their environment. Incomplete information may create another channel for contagion. If a shock in one region serves as a signal predicting a shock in another region, then a crisis in one region may create a self-fulfilling expectation of a crisis in another region.

We also exclude the effect of international currency markets in the propagation of financial crises from one country to another. Currency crises have been extensively studied, and Calvo (1995) and Chang and Velasco (1998), among others, have studied the interaction of the banking system and currency markets in a crisis; but the role of currency markets in financial contagion is left as a subject for future research.

The central aim of this paper is to provide some microeconomic foundations for financial contagion. Although the analysis may have some relevance to the recent Asian financial crisis, the model developed in this paper is not intended to be a description of any particular episode. If it does resemble any historical episode, it would be the banking crises in the United States in the late nineteenth and early twentieth centuries (Hicks 1989).

We take as our starting point the model presented in Allen and Gale (1998). The basic assumptions about technology and preferences have become the standard in the literature since the appearance of the Diamond and Dybvig (1983) model. There are three dates $t = 0, 1, 2$ and a large number of identical consumers, each
of whom is endowed with one unit of a homogeneous consumption good. At date 1, the consumers learn whether they are early consumers, who value consumption only at date 1, or late consumers, who value consumption only at date 2. Uncertainty about their preferences creates a demand for liquidity.

Banks have a comparative advantage in providing liquidity. At the first date, consumers deposit their endowments in the banks, which invest them on behalf of the depositors. In exchange, depositors are promised a fixed amount of consumption at each subsequent date, depending on when they choose to withdraw. The bank can invest in two assets. There is a short-term asset that pays a return of one unit after one period and there is a long-term asset that pays a return $r < 1$ after one period or $R > 1$ after two periods. The long asset has a higher return if held to maturity, but liquidating it in the middle period is costly, so it is not very useful for providing consumption to early consumers. The banking sector is perfectly competitive, so banks offer risk-sharing contracts that maximize depositors' ex ante expected utility, subject to a zero-profit constraint.

Using this framework, we are interested in constructing a model in which small shocks lead to large effects by means of contagion, more precisely, in which a shock within a single sector can spread to other sectors and lead to an economywide financial crisis. One view is that financial crises are purely random events, unrelated to changes in the real economy (Kindleberger 1978). The modern version of this view, developed by Diamond and Dybvig (1983) and others, is that bank runs are self-fulfilling prophecies. An alternative view is that financial crises are an inherent part of the business cycle (Mitchell 1941; Gorton 1988; Allen and Gale 1998). The disadvantage of treating contagion as a "sunspot" phenomenon is that, without some real connection between different regions, any pattern of correlations is possible. So sunspot theories are equally consistent with contagion and the absence of contagion. We are interested in establishing a stronger result, that under certain circumstances every equilibrium of the model must be characterized by contagion. This form of contagion must be driven by real shocks and real linkages between regions.

The economy consists of a number of regions. The number of early and late consumers in each region fluctuates randomly, but the aggregate demand for liquidity is constant. This allows for inter-regional insurance as regions with liquidity surpluses provide liquidity for regions with liquidity shortages. The provision of insurance can be organized through an interbank market in deposits. Suppose that region A has a large number of early consumers when region B has a low number of early consumers, and vice versa. Since regions
A and B are otherwise identical, their deposits are perfect substitutes. The banks exchange deposits at the first date before they observe the liquidity shocks. If region A has a higher than average number of early consumers at date 1, then banks in region A can meet their obligations by liquidating some of their deposits in the banks of region B. Region B is happy to oblige because it has an excess supply of liquidity in the form of the short asset. At the final date the process is reversed, as banks in region B liquidate the deposits they hold in region A to meet the above-average demand from late consumers in region B.

Interregional cross holdings of deposits work well as long as there is enough liquidity in the banking system as a whole. If there is an excess demand for liquidity, however, the financial linkages caused by these cross holdings can turn out to be a disaster. While cross holdings of deposits are useful for reallocating liquidity within the banking system, they cannot increase the total amount of liquidity. If the economywide demand from consumers is greater than the stock of the short asset, the only way to provide more consumption is to liquidate the long asset. This is very costly (see Shleifer and Vishny [1992] and Allen and Gale [1998] for a discussion of the costs of premature liquidation), so banks try to avoid liquidating the long asset whenever possible. In this case, they can avoid liquidating the long asset by liquidating their claims on other regions instead. This mutual liquidation of claims does not create any additional liquidity, however. It merely denies liquidity to the troubled region, and bank runs and bankruptcy may be the result. What begins as a financial crisis in one region can then spread by contagion to other regions because of the cross holdings of deposits.

The interbank market works quite differently from the retail market. In the latter, runs occur because deposit contracts commit banks to a fixed payment and banks must begin liquidating the long asset when they cannot meet liquidity demand from the short asset. In the interbank market the initial problem is caused by the fact that banks with an excess demand for liquidity cannot get anything from banks in other regions. This is the opposite of the problem in the retail market and, in contrast, cannot be solved by making the contracts discretionary or contingent since whatever their form they cancel each other out. Instead of being caused by the nature of interbank claims, spillovers and contagion result just from the fall in the value of bank assets in adjacent regions.

Whether the financial crisis does spread depends crucially on the pattern of interconnectedness generated by the cross holdings of deposits. If the interbank market is complete and each region is connected to all the other regions, the initial impact of a financial crisis
in one region may be attenuated. On the other hand, if the interbank market is *incomplete*, each region is connected with a small number of other regions. The initial impact of the financial crisis may be felt very strongly in those neighboring regions, with the result that they too succumb to a crisis. As each region is affected by the crisis, it prompts premature liquidation of the long asset, with a consequent loss of value, so that previously unaffected regions find that they too are affected because their claims on the region in crisis have fallen in value.

It is important to note the role of the free-rider problem in explaining the difference between a complete and an incomplete interbank market. There is a natural pecking order among different sources for liquidity. A bank will meet withdrawals first from the short asset and then from holdings in other regions, and only in the last resort will it choose to liquidate the long asset. Cross holdings are useful for redistributing liquidity, but they do not create liquidity; so when there is a global shortage of liquidity (withdrawals exceed short assets), the only solution is to liquidate long assets. If every region takes a small hit (liquidates a small amount of the long asset), there may be no need for a global crisis. This is what happens with complete markets: banks in the troubled region have direct claims on banks in every other region, and there is no way to avoid paying one’s share. With incomplete markets, banks in the troubled region have a direct claim only on the banks in adjacent regions. The banks in other regions pursue their own interests and refuse to liquidate the long asset until they find themselves on the front line of the contagion.

The notion of a region is intended as a metaphor for categories of banks that may differ along several dimensions. For example, some banks may be better at raising funds whereas other banks are better at lending them. Or it might be that banks focus on lending to different industries or in different regions and as a result have lending opportunities that are not perfectly correlated with their deposit base. In either case, an interbank market plays an important role in redistributing the funds efficiently. However, the existence of claims between different categories of banks opens up the possibility of contagion when one category is hit by a sudden demand for liquidity.

Our paper is related to a number of others. Perhaps the closest is that by Lagunoff and Schreft (1998), which studies the spread of crises in a probabilistic model. Financial linkages are modeled by assuming that each project requires two participants and each participant requires two projects. When the probability that one’s partner will withdraw becomes too large, all participants simultaneously with-
draw; this is interpreted as a financial crisis. The banking system plays no role in Lagunoff and Schreft's analysis. Rochet and Tirole (1996) use monitoring as a means of triggering correlated crises: if one bank fails, it is assumed that other banks have not been properly monitored and a general collapse occurs. Financial multipliers are modeled by Kiyotaki and Moore (1998). In their model, the impact of illiquidity at one link in the credit chain travels down the chain. Models of crises based on multiple equilibria are contained in Cole and Kehoe (1996) and Cooper and Corbae (1997). For a survey of recent work on crises, see Calomiris (1995).

The rest of the paper is organized as follows. In Section II, we present a model of liquidity preference based on Diamond and Dybvig (1983) and Allen and Gale (1998). In Section III, we characterize optimal risk sharing in terms of a planning problem subject to incentive constraints and show that the incentive-efficient allocation is in fact the same as the first-best. Section IV shows how the first-best allocation can be decentralized through a competitive banking system with an interbank market in deposits. Several different market structures are described, and each turns out to be consistent with the first-best. The robustness of this schema is tested in the next three sections. We do this by perturbing the model to allow for an (aggregate) excess demand for liquidity in some states of nature. In Section V, it is shown that with an incomplete interbank market and a high degree of interconnectedness, a liquidity shock that causes a crisis in one region will spread by contagion to others. In Section VI, we consider a complete interbank market and an even higher degree of connectedness. It is shown that, with the same size shock and the same model parameters, there is no contagion. In Section VII, it is shown that with an incomplete interbank market and a low degree of connectedness, there is again no contagion. So the interaction of connectedness and incompleteness appears to be conducive to contagion. Section VIII considers alternatives to an interbank deposit market for sharing risk between regions. Finally, Section IX considers extensions of the basic framework.

II. Liquidity Preference

In this section we describe a simple model in which stochastic liquidity preference provides a motive for risk sharing. The framework is based on Diamond and Dybvig (1983) and Allen and Gale (1998), with some significant differences.

There are three dates, $t = 0, 1, 2$. There is a single consumption good that serves as the numeraire. This good can also be invested in assets to produce future consumption. There are two types of
assets, a liquid asset and an illiquid asset. The liquid asset is represented by a storage technology. One unit of the consumption good invested in the storage technology at date $t$ produces one unit of the consumption good at date $t + 1$. Because the returns to this asset are available one period later, we refer to it as the short asset. The illiquid asset has a higher return but requires more time to mature. For this reason we call it the long asset. Investment in the long asset can take place only in the first period, and one unit of the consumption good invested in the long asset at the first date produces $R > 1$ units of output at the final date.

The long asset is not completely illiquid. Each unit of the long asset can be prematurely liquidated to produce $0 < r < 1$ units of the consumption good at the middle date. Here we assume that liquidation takes the form of physical depreciation of the asset, and the liquidation value is treated as a technological constant, the “scrap value.” In practice, it is more likely that assets are liquidated by being sold, in which case the liquidation value is determined by the market price. Introducing a secondary market on which assets can be sold would complicate the analysis without changing the qualitative features of the model. Allen and Gale (1998) incorporate an asset market and endogenize the liquidation values of assets. Their analysis confirms that the liquidation value will be low for appropriate parameter values.

The economy is divided into four ex ante identical regions, labeled A, B, C, and D. The regional structure is a spatial metaphor that can be interpreted in a variety of ways. The important thing for the analysis is that different regions receive different liquidity shocks. Any story that motivates different shocks for different (groups of) banks is a possible interpretation of the regional structure. So a region can correspond to a single bank, a geographical region within a country, or an entire country; it can also correspond to a specialized sector within the banking industry.

Each region contains a continuum of ex ante identical consumers (depositors). A consumer has an endowment equal to one unit of the consumption good at date 0 and nothing at dates 1 and 2. Consumers are assumed to have the usual Diamond-Dybvig preferences: with probability $\omega$ they are early consumers and value consumption only at date 1; with probability $1 - \omega$ they are late consumers and value consumption only at date 2. Then the preferences of the individual consumer are given by

$$U(c_1, c_2) = \begin{cases} u(c_1) & \text{with probability } \omega \\ u(c_2) & \text{with probability } 1 - \omega, \end{cases}$$
TABLE 1

</tr>
</tbody>
</table>

where $c_t$ denotes consumption at date $t = 1, 2$. The period utility functions $u(\cdot)$ are assumed to be twice continuously differentiable, increasing, and strictly concave.

The probability $\omega$ varies from region to region. Let $\omega_i$ denote the probability of being an early consumer in region $i$. There are two possible values of $\omega_i$, a high value and a low value, denoted $\omega_H$ and $\omega_L$, where $0 < \omega_L < \omega_H < 1$. The realization of these random variables depends on the state of nature. There are two equally likely states $S_1$ and $S_2$, and the corresponding realizations of the liquidity preference shocks are given in table 1. Note that, ex ante, each region has the same probability of having a high liquidity preference shock. Also, the aggregate demand for liquidity is the same in each state: half the regions have a high liquidity preference and half have a low liquidity preference.

All uncertainty is resolved at date 1 when the state of nature $S_1$ or $S_2$ is revealed and each consumer learns whether he is an early or late consumer. A consumer’s type is not observable, so late consumers can always imitate early consumers.

Before we introduce the banking sector into our story, it will be convenient to characterize the optimal allocation of risk.

III. Optimal Risk Sharing

In this section we characterize optimal risk sharing as the solution to a planning problem. Since consumers are ex ante identical, it is natural to treat consumers symmetrically. For this reason, the planner is assumed to make all the investment and consumption decisions to maximize the unweighted sum of consumers’ expected utility.

We begin by describing the planner’s problem under the assumption that the planner can identify early and late consumers. The symmetry and concavity of the objective function and the convexity of the constraints simplify the problem considerably. (1) Since there is no aggregate uncertainty, the optimal consumption allocation will be independent of the state. (2) Since the consumers in one region are ex ante identical to consumers in another region, all consumers
will be treated alike. Without loss of generality, then, we can assume that every early consumer receives consumption $c_1$ and every late consumer receives $c_2$, independently of the region and state of nature. At the first date, the planner chooses a portfolio $(x, y) \succeq 0$ subject to the feasibility constraint

$$x + y \leq 1,$$

(1)

where $x$ and $y$ are the per capita amounts invested in the long and short assets, respectively. (3) Since the total amount of consumption provided in each period is a constant, it is optimal to provide for consumption at date 1 by holding the short asset and to provide for consumption at date 2 by holding the long asset. Let the average fraction of early consumers be denoted by $\gamma = (\omega_h + \omega_l)/2$. Then the feasibility constraint at date 1 is

$$\gamma c_1 \leq y$$

(2)

and the feasibility constraint at date 2 is

$$(1 - \gamma) c_2 \leq Rx.$$  

(3)

At date 0, each consumer has an equal probability of being an early or a late consumer, so the ex ante expected utility is

$$\gamma u(c_1) + (1 - \gamma) u(c_2),$$

(4)

and this is what the planner seeks to maximize, subject to the constraints (1), (2), and (3). The unique solution to this unconstrained problem is called the first-best allocation.

The first-best allocation satisfies the first-order condition $u'(c_1) \succeq u'(c_2)$. Otherwise, the objective function could be increased by using the short asset to shift some consumption from early to late consumers. Thus the first-best allocation automatically satisfies the incentive constraint

$$c_1 \succeq c_2,$$

(5)

which says that late consumers find it weakly optimal to reveal their true type rather than pretend to be early consumers. The incentive-efficient allocation maximizes the objective function (4) subject to the feasibility constraints (1), (2), and (3) and the incentive constraint (5). What we have shown is that the incentive-efficient allocation is the same as the first-best allocation.

**Proposition 1.** The first-best allocation $(x, y, c_1, c_2)$ is equivalent to the incentive-efficient allocation, so the first-best can be achieved even if the planner cannot observe the consumers' types.

In order to achieve the first-best, the planner has to transfer resources among the different regions. In state $S_1$, for example, there
are $\omega_H$ early consumers in regions A and C and $\omega_L$ early consumers in regions B and D. Each region has $\gamma c_1$ units of the short asset, which provide $\gamma c_1$ units of consumption. So regions A and C each have an excess demand for $(\omega_H - \gamma) c_1$ units of consumption and regions B and D each have an excess supply of $(\gamma - \omega_L) c_1 = (\omega_H - \gamma) c_2$ units of consumption. By reallocating this consumption, the planner can satisfy every region’s needs. At date 2, the transfers flow in the opposite direction because regions B and D have an excess demand of $(\omega_H - \gamma) c_2$ units each and regions A and C have an excess supply of $(\omega_H - \gamma) c_2$ units each.

IV. Decentralization

In this section we describe how the first-best allocation can be decentralized by a competitive banking sector. There are two reasons for focusing on the first-best. One is technical: it turns out that it is much easier to characterize the equilibrium conditions when the allocation is the first-best. The second reason is that, as usual, we are interested in knowing under what conditions the market “works.” For the moment, we are concerned only with the feasibility of decentralization. The optimality of the banks’ behavior is discussed in Section IXA.

The role of banks is to make investments on behalf of consumers and to insure them against liquidity shocks. We assume that only banks invest in the long asset. This gives the bank two advantages over consumers. First, the banks can hold a portfolio consisting of both types of assets, which will typically be preferred to a portfolio consisting of the short asset alone. Second, by pooling the assets of a large number of consumers, the bank can offer insurance to consumers against their uncertain liquidity demands, giving the early consumers some of the benefits of the high-yielding long asset without subjecting them to the high costs of liquidating the long asset prematurely at the second date.

In each region there is a continuum of identical banks. We focus on a symmetric equilibrium in which all banks adopt the same behavior. Thus we can describe the decentralized allocation in terms of the behavior of a representative bank in each region.

Without loss of generality, we can assume that each consumer deposits his endowment of one unit of the consumption good in the representative bank in his region. The bank invests the deposit in a portfolio $(x', y') \succeq 0$ and, in exchange, offers a deposit contract $(c_1', c_2')$ that allows the depositor to withdraw either $c_1'$ units of consumption at date 1 or $c_2'$ units of consumption at date 2. Note that the deposit contract is not contingent on the liquidity shock in re-
region $i$. In order to achieve the first-best through a decentralized banking sector, we need to put $(x', y') = (x, y)$ and $(c_1', c_2') = (c_1, c_2)$, where $(x, y, c_1, c_2)$ is the first-best allocation.

The problem with this approach is that, while the investment portfolio satisfies the bank's budget constraint $x + y \leq 1$ at the first date, it will not satisfy the budget constraint at the second date. The planner can move consumption between regions, so he needs to satisfy only the average constraint $\gamma c_1 \leq \gamma$. The representative bank, on the other hand, has to face the possibility that the fraction of early consumers in its region may be above average, $\omega_{i1} > \gamma$, in which case it will need more than $\gamma$ to satisfy the demands of the early consumers. It can meet this excess demand by liquidating some of the long asset, but then it will not have enough consumption to meet the demands of the late consumers at date 2. In fact, if $r$ is small enough, the bank may not be able to pay the late consumers even $c_1$. Then the late consumers will prefer to withdraw at date 1 and store the consumption good until date 2, thus causing a bank run.

There is no overall shortage of liquidity, it is just badly distributed. One way to allow the banks to overcome the maldistribution of the liquidity is to introduce an interbank market in deposits.

A. The Interbank Deposit Market

Suppose that banks are allowed to exchange deposits at the first date. This case of complete markets is illustrated in figure 1. Each region is negatively correlated with two other regions. We therefore assume that every bank in region $i$ holds $z' = (\omega_{i1} - \gamma)/2 > 0$ deposits in each of the regions $j \neq i$. Since bank deposits are identical and worth one unit each at the first date, the representative bank's budget constraint will still be satisfied at date 0. At the beginning of the
second period the state of nature $S$ is observed, and the banks have to adjust their portfolios to satisfy their budget constraints. If the region has a high demand for liquidity, $\omega' = \omega_H$, it liquidates all its deposits in other regions. On the other hand, if it has a low demand for liquidity, $\omega' = \omega_L$, it retains the deposits it holds in the other regions until the final date.

Consider the budget constraint of a bank in a region with a high demand for liquidity. It must pay $c_1$ to the fraction $\omega_H$ of early consumers in its own region and also redeem the $z' = (\omega_H - \gamma)/2$ deposits of the other high-demand region. So the total demand for repayment is $[\omega_H + [(\omega_H - \gamma)/2]]c_1$. On the other side of the ledger, it has $y$ units of the short asset and claims to $3z' = 3(\omega_H - \gamma)/2$ deposits in the other three regions. Thus the budget constraint that must be satisfied is

$$\left(\omega_H + \frac{\omega_H - \gamma}{2}\right)c_1 = y + \frac{3(\omega_H - \gamma)}{2},$$

which simplifies to the planner's constraint $\gamma c_1 = y$. A bank in a region with low liquidity demand must pay $c_1$ to a fraction $\omega_L$ of its own depositors and redeem $2z' = \omega_H - \gamma$ deposits from the banks in the regions with high liquidity demand. It has $y$ units of the short asset to meet these demands, so the budget constraint that must be satisfied is

$$[\omega_L + (\omega_H - \gamma)]c_1 = y.$$

Since $\omega_H - \gamma = \gamma - \omega_L$, this equation simplifies to the planner's constraint $\gamma c_1 = y$. In both cases, the cross holdings of deposits allow the banks to meet the demands of their depositors without liquidating the long asset.

At the last date, all the banks liquidate their remaining assets, and it is easy to show that if the budget constraints at the second date are satisfied, the budget constraints at the third date are automatically satisfied too. For example, the budget constraint at date 2 for a region that had high liquidity preference at date 1 will be

$$[ (1 - \omega_H) + (\omega_H - \gamma) ]c_2 = Rx,$$

where the left-hand side is the demand for withdrawals, comprising the demand of the late consumers in the region $1 - \omega_H$ plus the demand from the two regions with low liquidity preference, $\omega_L = \omega_H - \gamma$. On the right-hand side, we have the liquidation value of the long asset $Rx$. This simplifies to the planner's constraint $(1 - \gamma) c_2 =$
Rx. The same is true of the budget constraint for the regions with a low liquidity shock:

\[
\left[ (1 - \omega_L) + \frac{\omega_H - \gamma}{2} \right]c_2 = Rx + 3 \left( \frac{\omega_H - \gamma}{2} \right)c_2.
\]

Thus, by shuffling deposits among the different regions, banks are able to satisfy their budget constraints in each state \(S\) and at each date \(t = 0, 1, 2\) while providing their depositors with the first-best consumption allocation through a standard deposit contract.

**B. Incompleteness in the Interbank Deposit Market**

The interbank market in the preceding section is complete in the sense that a bank in region \(i\) can hold deposits in every other region \(j \neq i\). In some cases, this may not be realistic. The banking sector is interconnected in a variety of ways, but transaction and information costs may prevent banks from acquiring claims on banks in remote regions. To the extent that banks specialize in particular areas of business or have closer connections with banks that operate in the same geographical or political unit, deposits may tend to be concentrated in "neighboring" banks. To capture this effect, which is crucial in the sequel, we introduce the notion of incompleteness in the interbank market by assuming that banks in region \(i\) are allowed to hold deposits in some but not all of the other regions. For concreteness we assume that banks in each region hold deposits only in one adjacent region, as shown in figure 2. It can be seen that banks in region A can hold deposits in region B, banks in region B can hold deposits in region C, and so on.
As before we suppose that the representative bank in region \( i \) holds an investment portfolio \((x', y') = (x, y)\) and offers a deposit contract \((c_1, c_2') = (c_1, c_2)\). We also assume that the bank holds \( x^i = \omega_H - \gamma \) deposits in the adjacent region at the first date; that is, the bank in region A holds \( \omega_H - \gamma \) deposits in region B, and so on. The first-period budget constraint is satisfied as before because the exchanges of deposits, having the same values, cancel out, leaving the budget constraint \( x + y \leq 1 \).

At date 1 the aggregate state is observed, and banks and consumers learn the liquidity shock in each region. As before, we need only to distinguish regions according to whether they have high or low demands for liquidity. Regions with the high liquidity shock \( \omega_H \) liquidate their deposits in other banks at the second date whereas banks with the low liquidity shock \( \omega_L \) do not. The market structure that is assumed here has the property that every region with a high liquidity shock has deposits in a region with a low liquidity shock, and vice versa. The budget constraint of a region with high liquidity shocks is

\[
\omega_H c_1 = y + (\omega_H - \gamma) c_1,
\]

and the budget constraint of a region with low liquidity shocks is

\[
[\omega_L + (\omega_H - \gamma)] c_1 = y.
\]

Substituting \( \omega_H - \gamma = \gamma - \omega_L \) and simplifying, we see that both constraints are equivalent to the planner’s constraint \( \gamma c_1 = y \). Likewise, at the final date the budget constraints for the regions with high and low liquidity shocks are, respectively,

\[
[(1 - \omega_H) + (\omega_H - \gamma)] c_2 = Rx
\]

and

\[
(1 - \omega_L) c_2 = Rx + (\omega_H - \gamma) c_2,
\]

and both are equivalent to the planner’s constraint \((1 - \gamma) c_2 = Rx\).

So even if the interbank deposit market is incomplete, it is possible to satisfy the budget constraints by shuffling deposits through the interbank market. However, although it is possible to achieve the first-best with either complete or incomplete markets, we shall see that the implications for financial fragility are very different in the two cases.

One interesting feature of the market structure in figure 2 is that, although each region is relying on just its neighbor for liquidity, the entire economy is connected. Region A holds deposits in region B, which holds deposits in region C, and so on. In fact, this is unavoidable given the market structure assumed. Consider the alternative
market structure shown in figure 3. Region A holds deposits in region B and region B holds deposits in region A. Likewise, region C holds one unit of deposits in region D and region D holds one unit of deposits in region C. This market structure is more incomplete than the one in figure 2, and the pattern of holdings in figure 2 is incompatible with it. However, it is possible to achieve the first-best through the pattern of holdings in figure 3. This is true even though the economy is disconnected, since regions A and B trade with each other but not with regions C and D and regions C and D trade with each other but not with regions A and B. Again, these patterns do not seem to have any significance as far as achieving the first-best is concerned; but they turn out to have striking differences for financial fragility.

V. Fragility

To illustrate the financial fragility of the optimal risk-sharing allocation, we use the decentralization results from Section IV. Then we perturb the model to allow for the occurrence of a state $\bar{S}$ in which the aggregate demand for liquidity is greater than the system’s ability to supply liquidity and show that this can lead to an economywide crisis.

The market structure is assumed to be given by figure 2. The corresponding allocation requires each bank to hold an initial portfolio of investments $(x, y)$ and offer a deposit contract $(c_1, c_2)$, where $(x, y, c_1, c_2)$ is the first-best allocation. In order to make this deposit contract feasible, the representative bank in each region holds $z = \omega H - \gamma$ deposits in the adjacent region. Note that $z$ is the minimal amount that is needed to satisfy the budget constraints. It will become apparent that larger cross holdings of deposits, while consis-

tent with the first-best in Section IV, would make the contagion problem worse.

Now, let us take the allocation as given and consider what happens when we "perturb" the model. By a perturbation we mean the realization of a state $\bar{S}$ that was assigned zero probability at date 0 and has a demand for liquidity that is very close to that of the states that do occur with positive probability. Specifically, the liquidity shocks are given in table 2. In state $\bar{S}$, every region has the previous average demand for liquidity $\gamma$ except for region A, where the demand for liquidity is somewhat higher at $\gamma + \epsilon$. The important fact is that the average demand for liquidity across all four regions is slightly higher than in the normal states $S_1$ and $S_2$. Since the abnormal state $\bar{S}$ occurs with zero probability, it will not change the allocation at date 0. In states $S_1$ and $S_2$ the continuation equilibrium will be the same as before at date 1; in state $\bar{S}$ the continuation equilibrium will be different.

In the continuation equilibrium beginning at date 1, consumers will optimally decide whether to withdraw their deposits at date 1 or date 2, and banks will liquidate their assets in an attempt to meet the demands of their depositors. Early consumers always withdraw at date 1; late consumers will withdraw at date 1 or date 2 depending on which gives them the larger amount of consumption. Because we want to focus on essential bank crises, we assume that late consumers will always withdraw their deposits at date 2 if it is (weakly) optimal for them to do so. Banks are required to meet their promise to pay $c_1$ units of consumption to each depositor who demands withdrawal at date 1. If they cannot do so, they must liquidate all their assets at date 1. As in Allen and Gale (1998), the proceeds of the liquidation are split pro rata among depositors (i.e., we do not assume first come, first served). If the bank can meet its obligations at date 1, then the remaining assets are liquidated at date 2 and given to the depositors who have waited until date 2 to withdraw. In the rest of this section, we describe the continuation equilibrium at date 1 in state $\bar{S}$, assuming the actions consistent with the first-best at date 0.
A. The Liquidation “Pecking Order”

At date 1 a bank can find itself in one of three conditions. A bank is said to be solvent if it can meet the demands of every depositor who wants to withdraw (including banks in other regions) by using only its liquid assets, that is, the short asset and the deposits in other regions. The bank is said to be insolvent if it can meet the demands of its deposits but only by liquidating some of the long asset. Finally, the bank is said to be bankrupt if it cannot meet the demands of its depositors by liquidating all its assets.

These definitions are motivated by the assumption that banks will always find it preferable to liquidate assets in a particular order at date 1. We call this the “pecking order” for liquidating assets, and it goes as follows: first, the bank liquidates the short asset, then it liquidates deposits, and finally it liquidates the long asset. To ensure that the long asset is liquidated last, we need an additional assumption,

$$\frac{R}{r} > \frac{c_2}{c_1},$$

which is maintained in the sequel. Since the first-best consumption allocation $c_1$, $c_2$ is independent of $r$ (this variable does not appear in the first-best problem in Sec. III), we can always ensure that condition (6) is satisfied by choosing $r$ sufficiently small.

Each of the three assets offers a different cost of obtaining current (date 1) consumption in terms of future (date 2) consumption. The cheapest is the short asset. One unit of the short asset is worth one unit of consumption today, and if reinvested in the short asset, it is worth one unit of consumption tomorrow. So the cost of obtaining liquidity by liquidating the short asset is one. Similarly, by liquidating one unit of deposits, the bank gives up $c_2$ units of future consumption and obtains $c_1$ units of present consumption. So the cost of obtaining liquidity by liquidating deposits is $c_2/c_1$. From the first-order condition $u'(c_1) = Ru'(c_2)$, we know that $c_2/c_1 > 1$. Finally, by liquidating one unit of the long asset, the bank gives up $R$ units of future consumption and obtains $r$ units of present consumption. So the cost of obtaining liquidity by liquidating the long asset is $R/r$. Thus we have derived the pecking order, short assets, deposits, long assets:

$$1 < \frac{c_2}{c_1} < \frac{R}{r}.$$
The preceding argument assumes that the banks in other regions are not bankrupt. The bankruptcy rules require all assets to be liquidated immediately, so all deposit holders in a bankrupt institution will want to liquidate their deposits immediately regardless of their own condition.

B. Liquidation Values

The value of a deposit at date 1 is $c_i$ if the bank is not bankrupt, and it is equal to the liquidation value of all the bank’s assets if the bank is bankrupt. Let $q^i$ denote the value of the representative bank’s deposits in region $i$ at date 1. If $q^i < c_i$, then all the depositors will withdraw as much as they can at date 1. In particular, the banks in other regions will be seeking to withdraw their claims on the bank at the same time the bank is trying to redeem its claims on them. All depositors must be treated equally; that is, every depositor gets $q^i$ from the bank for each unit invested at the first date, whether the depositor is a consumer or a bank from another region. Then the values of $q^i$ must be determined simultaneously. Consider the representative bank in region A, for example. If all the depositors withdraw, the total demands will be $1 + z$, since the banks in region D hold $z$ deposits and the consumers in region A hold one deposit. The liabilities of the bank are valued at $(1 + z)q^A$. The assets consist of $y$ units of the short asset, $x$ units of the long asset, and $z$ deposits in region B. The assets are valued at $y + rx + zq^B$. The equilibrium values of $q^A$ must equate the value of assets and liabilities:

$$q^A = \frac{y + rx + zq^B}{1 + z}.$$  

(7)

A similar equation must hold for any region $i$ in which $q^i < c_i$.

If $q^B = c_1$, then we can use this equation to calculate the value of $q^A$; but if $q^B < c_1$, then we need another equation to determine $q^B$; this equation will include the value of $q^C$, and so on.

C. Buffers and Bank Runs

Suppose that a bank is insolvent and has to liquidate some of the long asset. For the moment, we assume that the late consumers wait until the last date, and we ignore the role of banks in other regions. How much can the bank afford to give the consumers at the first date? The bank must give the late consumers at least $c_1$ at date 2; otherwise they would be better off withdrawing at date 1. So a bank with a fraction $\omega$ of early consumers must keep at least $(1 -$
\( \omega \) \( c_1 / R \) units of the long asset to satisfy the late consumers at date 2. Then the amount of the long asset that can be liquidated at date 1 is \( x - \lfloor (1 - \omega) c_1 / R \rfloor \), and the amount of consumption that can be obtained by liquidating the long asset without causing a run is

\[
b(\omega) \equiv r \left[ x - \frac{(1 - \omega) c_1}{R} \right].
\]

We call \( b(\omega) \) the bank’s buffer.

In region A, the bank has \( y = \gamma c_1 \) units of the short asset. The fraction of early consumers is \( \gamma + \epsilon \) in state \( S \), so in order to pay each early consumer \( c_1 \) units of consumption, the bank will have to get \( \epsilon c_1 \) units of consumption by liquidating the long asset. This is feasible, without any help from the banks in other regions, if and only if the increased demand for liquidity \( \epsilon c_1 \) is less than the buffer:

\[
\epsilon c_1 \leq b(\gamma + \epsilon).
\]

In most of what follows, we assume that condition (8) is violated. In other words, if region A had to remain self-sufficient, it would be bankrupt because there is no way it can feasibly offer its late consumers \( c_1 \) at date 2 (to prevent a run) and meet the demands of its early consumers for \( c_1 \) at date 1.

When \( \epsilon > 0 \) is small enough to satisfy the inequality (8), the banks in region A are insolvent, but there are no repercussions for the banks in other regions. The late consumers in region A are worse off because the premature liquidation of the long asset at date 1 prevents the bank from paying \( c_2 \) to depositors at date 2. (The pecking order implies that the banks in regions B, C, and D will liquidate their deposits in regions C, D, and A, respectively, rather than liquidate the long asset.)

When \( \epsilon \) is large enough to violate condition (8), banks in region A will be bankrupt. Although they have deposits in region B, these deposits are of no use as long as the value of deposits in region A is \( q^A = c_1 \). Other regions will liquidate their deposits in order to avoid liquidating the long asset. As long as all the deposits have the same value, the mutual withdrawals simply cancel out. Once the banks in region A are bankrupt, there will be a spillover effect to region D. A deposit in region D is worth \( q^D = c_1 \) and a deposit in region A is worth \( q^A < c_1 \), so banks in region D suffer a loss when cross holdings of deposits are liquidated. If \( \epsilon \) is not too large, this spillover effect will make region D banks insolvent but will not force them into bankruptcy.

Once bankruptcy has occurred in region A, all consumers are withdrawing at date 1 and the distinction between early and late
consumers is immaterial. A further increase in $\epsilon$ will have no effect. The spillover effect to region D may be larger or smaller than region D’s buffer. If the spillover is smaller than the buffer, the banks in region D will lose part of their buffer but the contagion will spread no further. If the spillover is larger than the buffer in region D, then region D banks will be bankrupt too.

The size of the spillover will depend on a number of parameters, especially the size of the liquidation value $r$. If $r$ is small, then the loss of asset value in region A is large and the spillover effect is large. A small value of $r$ also makes the buffer in each region smaller. Thus there are two ways in which a small liquidation value $r$ makes it more likely that the spillover will exceed the buffer in region D.

The liquidation of region D’s long assets will cause a loss to banks in region C, and this time the accumulated spillover effect is already large enough that region C too will be bankrupt. As we go from region to region the spillover gets larger and larger, because more regions are in bankruptcy and more losses have accumulated from liquidating the long asset. So once region D goes bankrupt, all the regions go bankrupt. This result is summarized in proposition 2 below.

As this informal discussion suggests, two conditions must be satisfied in order for the initial shock to region A to spread to all the other regions. First, the liquidity preference shock in region A must exceed the buffer in region A:

$$\epsilon c_1 > b(\gamma + \epsilon).$$  \hspace{1cm} (9)

Second, the spillover effect to region D must exceed the buffer in region D. A lower bound for the spillover effect is $z(c_1 - \bar{q}^A)$, where $z$ is the amount of deposits held and $\bar{q}^A$ is an upper bound on the value of the deposits in region A under bankruptcy. To derive the upper bound $\bar{q}^A$, we use equation (7) and assume that $q^A = c_1$:

$$q^A \leq \bar{q}^A = \frac{y + rx + zc_1}{1 + z}. \hspace{1cm} (10)$$

Then a sufficient condition for the spillover to exceed the buffer in region D is

$$z(c_1 - \bar{q}^A) > b(\gamma).$$  \hspace{1cm} (11)

The term $zc_1$ is the amount promised to the banks in region C, and $z\bar{q}^A$ is the upper bound on the value of deposits in region A. Hence the left-hand side of the condition is the difference between liabilities and the upper bound on assets in the interbank deposit market.
for region D. If this exceeds region D's buffer, the spillover will force region D banks into bankruptcy.

Proposition 2. Consider the model with market structure described in figure 2 and perturb it by the addition of the zero probability state $\bar{S}$. Suppose that each bank chooses an investment portfolio $(x, y, z)$ and offers a deposit contract $(c_1, c_2)$, where $(x, y)$ is the first-best investment portfolio, $(c_1, c_2)$ is the first-best consumption allocation, and $z = \omega_{nt} - \gamma$. Suppose that conditions (9) and (11) are satisfied. Then, in any continuation equilibrium, the banks in all regions must go bankrupt at date 1 in state $\bar{S}$.

Proof: The proof requires several steps.

Step 1.—We first suppose that there is a continuation equilibrium in which $q^i = c_1$ in every region $i$ and show that this leads to a contradiction. The demand for deposits from early consumers is $\gamma + \epsilon$ in region A and $\gamma$ in regions B, C, and D. The stock of the short asset is $\gamma = \gamma c_1$, so there is an aggregate excess demand for liquidity that can be met only by liquidating the long asset in some region. To avoid liquidating the long asset, banks must redeem at least as many deposits as are withdrawn by banks from other regions. Since no bank wants to liquidate the long asset if it can be avoided, the only equilibrium is one in which all banks simultaneously withdraw their deposits in banks in other regions at date 1. These mutual withdrawals offset each other, so each region is forced to be self-sufficient; that is, no region is able to get extra liquidity from the other regions.

We have already seen that self-sufficiency implies that the banks in region A are bankrupt. Thus we have a contradiction that implies that the banks in some region must be bankrupt. In fact, the banks in region A must be bankrupt. By the earlier argument, $q^i < c_1$ for some $i$ implies that all banks will withdraw their deposits in other regions. Then either $q^B = c_1$ and region A receives no net inflows from the interbank market or $q^B < c_1$ and the situation is even worse because region A loses money on its deposits in region B. In either case, $q^A = c_1$ is impossible because of condition (9).

Step 2.—Having established that banks in region A must be bankrupt, we next show that the financial crisis must extend to other regions. Consider region D first. For the reasons explained above, all banks will be liquidating their deposits in other regions in any continuation equilibrium in state $\bar{S}$. An upper bound on the liquidation value $q^A$ of the deposits in region A is obtained by assuming that $q^B = c_1$, that is, $q^A \leq \bar{q}^A$. If banks in region D are not bankrupt, the liabilities of the banks in region D are $(\gamma + z) c_1$, because a fraction $\gamma$ of consumers withdraw early, the banks in region C withdraw $z$ deposits, and each deposit is worth $c_1$. The liquid assets of the bank are worth $y + zq^A$, and the buffer $b(\gamma)$ is the most that can be ob-
tained from liquidating the long asset without violating the incentive constraint. So, to avoid bankruptcy, it must be the case that
\[(\gamma + z)c_1 \leq y + b(\gamma) + zq^A \leq y + b(\gamma) + \bar{q}^A.\]

Since \(\gamma c_1 = y\), this inequality implies that \(z(c_1 - \bar{q}^A) \leq b(\gamma)\), contradicting condition (11). Thus the banks in region D must be bankrupt also.

Step 3.—The argument from step 2 can be continued by induction. In fact, since we know that \(\bar{q}^A < c_1\), we must have \(q^D < \bar{q}^A\). Then it is easier to violate the nonbankruptcy condition in region C than it was in region D, and this shows that \(q^C < q^A\). Then using the same argument, we have \(q^i < q^A\) for every region \(i\). All regions are in bankruptcy, and the only possible continuation equilibrium is one in which \(q^i = y + nx < c_1\) for \(i = A, B, C, D\). Q.E.D.

VI. Robustness

The incompleteness of markets in figure 2 is essential to the contagion result in the following sense. There exist parameter values for which any equilibrium with incomplete markets involves runs in state \(S\) (this is the set of parameter values characterized in Sec. V). For the same parameter values, we can find an equilibrium with complete markets that does not involve runs in state \(S\).

To see this, we go back to the complete markets equilibrium in Section IV. The values of the investment portfolio \((x, y)\) and the deposit contract \((c_1, c_2)\) are the same; but to make the first-best allocation feasible at dates 1 and 2, the representative bank holds \(z/2 = (\omega_H - \gamma)/2\) deposits in each of the other regions. The claim on any one region is smaller than in the equilibrium in Section V, but the total claim \(3z/2\) is larger. Again, \(z/2\) is the smallest amount of deposits consistent with feasibility.

Consider now what happens in a continuation equilibrium at date 1 when state \(S\) occurs, assuming that the actions at date 0 have not changed. We assume, of course, that the conditions of proposition 2 continue to hold. Using exactly the same argument as before, we can show that banks in region A are bankrupt: there is an aggregate excess demand for liquidity, the other regions will not provide liquidity, and because condition (8) is violated the banks in region A cannot meet their depositors' demands. The question is whether this requires that the other regions should also experience bankruptcy.

To address this question, we have to calculate the liquidation value of the deposits in region A. Assuming that none of the other regions
is bankrupt, we observe that the assets are valued at \( y + rx + 3(z/2)e_1 \) and the liabilities are valued at \([1 + (3z/2)]q^A\), so

\[
\bar{q}^{A*} = \frac{y + rx + 3(z/2)e_1}{1 + (3z/2)}.
\] (12)

The loss to each bank in regions \( j \neq A \) because of the collapse of banks in region A is \( (z/2)(e_1 - \bar{q}^{A*}) \), and since the bank’s holding of the short asset \( y \) is just enough to satisfy its own early consumers, the bank will be insolvent, but not bankrupt, if and only if this amount is less than or equal to the buffer:

\[
\left(\frac{z}{2}\right)(e_1 - \bar{q}^{A*}) \leq b(\gamma).
\] (13)

Condition (13) can be satisfied even though conditions (8) and (11) are violated because the financial interdependence, measured by \( z/2 \), is smaller.

The special nature of the incompleteness of markets in figure 2 is discussed in the following section.

**VII. Containment**

The critical ingredient in the example of contagion analyzed in Section V is that any two regions are connected by a chain of overlapping bank liabilities. Banks in region A have claims on banks in region B, which in turn have claims on banks in region C, and so on. If we could cut this chain at some point, the contagion that begins with a small shock in region A would be contained in a subset of the set of regions.

Consider the incomplete market structure in figure 3 and the allocation that implements the first-best, which was described in Section IV. The allocation requires banks in regions A and B to have claims on each other and banks in regions C and D to have claims on each other, but there is no connection between the region \( \{A, B\} \) and the region \( \{C, D\} \). If state \( S \) occurs, the excess demand for liquidity will cause bankruptcies in region A, and they may under certain conditions spread to region B; but there is no reason why they should spread any further. Banks in regions C and D are simply not connected to the troubled banks in regions A and B.

Comparing the three market structures we have considered so far—complete markets in figure 1, incomplete markets in figure 2, and the disconnected market structure in figure 3—we can see that there is a nonmonotonic relationship between completeness or in-
completeness of markets and the extent of the financial crisis in state $\bar{S}$. With the complete markets structure of figure 1 the crisis is restricted to region A, with the market structure in figure 2 the crisis extends to all regions, and with the market structure in figure 3 the crisis is restricted to regions A and B.

It could be argued that the market structures are not monotonically ordered: the complete markets network does contain the other two, but the paths in the network in figure 3 are not a subset of the network in figure 2. This could be changed by adding paths to figure 2, but then the equilibrium of figure 3 would also be an equilibrium of figure 2. This raises an obvious but important point: that contagion depends on the endogenous pattern of financial claims. An incomplete market structure like the one in figure 2 may preclude a complete pattern of financial connectedness and thus encourage financial contagion; but a complete market structure does not imply the opposite: even with complete markets, there may be an endogenous choice of overlapping claims that causes contagion. In fact, the three equilibria considered so far are all consistent with the complete market structure. There are additional equilibria for the economy with the complete market structure. Like the three considered so far, they achieve the first-best in states $S_1$ and $S_2$ but have different degrees of financial fragility in the unexpected state $\bar{S}$, depending on the patterns of interregional deposit holding.

What is important about the market structure in figure 2, then, is that the pattern of interregional cross holdings of deposits that promotes the possibility of contagion is the only one consistent with this market structure. Since we are interested in contagion as an essential phenomenon, this market structure has a special role. The complete markets economy, by contrast, has equilibria with and without contagion and provides a weaker case for the likelihood of contagion.

VIII. Alternative Interbank Markets

In our analysis of contagion, interbank deposits play an important role. Without the interlinkages they provide, the financial crisis would not spread between regions. An important issue is whether there exist alternatives to interbank deposits that achieve risk sharing in states $S_1$ and $S_2$ but avoid contagion in state $\bar{S}$. In the context of banks' interactions with ordinary depositors in the retail market, it is well known from the work of Diamond and Dybvig (1983) and before that the combination of liquid liabilities (in the form of demand deposits) and illiquid assets is essential to the theory of bank
runs. Runs can be prevented by making the amount paid out contingent on asset returns or by "suspending convertibility." The rationale for standard deposit contracts is not entirely clear, though some attempts have been made (see, e.g., Calomiris and Kahn 1991); but at least there is clear empirical evidence that deposit contracts are used. However, in the context of interbank markets, where deposit contracts are not as widely used, it is natural to ask whether there are feasible alternatives that would prevent runs.

Once we accept that consumers hold demand deposits, it is inevitable that banks in region A will come under pressure in state $\bar{S}$. What leads to contagion is the fact that (a) banks have an incentive to hoard liquidity when there is an excess demand for it and that (b) once bankruptcies have occurred in one or more regions, spillovers result from the ex ante claims that banks hold on each other. The crucial property of the claims traded on the interbank market is not that they are noncontingent. Rather, it is the fact that banks, by simultaneously liquidating their claims on each other, can effectively cancel them until at least one region goes bankrupt. Once banks in one region are bankrupt, the claims on that region have lower value and a spillover to its creditors follows.

Making the interbank claims contingent would not change the operation of the contagion. A similar result holds if the security traded on the interbank market is contingent on the state or on the level of demand for liquidity. As long as the holdings are symmetric across regions and the liquidation of cross holdings nets out to zero, so that region A has to find additional liquidity on its own, there will be contagion when the shock in region A is sufficiently large and the conditions of proposition 2 are satisfied.

This argument shows us that the use of demand deposits in the interbank market is not analogous to the use of demand deposits in the retail market. The two markets operate in very different ways. In the retail market, it is generally accepted that suspension of convertibility would prevent a bank run. The opposite is true in the interbank market. To illustrate this idea, suppose that interbank deposits are not payable on demand. Instead, banks can refuse payment at their own discretion. This kind of contract in the interbank market will support the first-best allocation (when the probability of $\bar{S}$ is zero), but it clearly will not prevent contagion in state $\bar{S}$. The reason is that banks will invoke their right to delay payment whenever they would otherwise have to liquidate the long asset. The option to delay payment is no different from using claims on other regions to cancel out the claims of those regions in the earlier analysis. The result in both cases is that banks in region A will have to
satisfy the extra demand $\epsilon$ from ordinary depositors in state $\bar{S}$ from their own resources. This entails liquidating the long asset, and when their buffer is exhausted, it entails bankruptcy.

This argument shows that provided that there are ex ante contracts between banks that are signed at date 0, a contagion will occur even if contracts are not demand deposits. However, if liquidity was provided on an ex post basis, there would be no possibility of contagion. Suppose, for example, that instead of an interbank market for deposits at the first date, there is an interbank market for one-period loans at the second date. Then a bank that finds it has an excess demand for liquidity at date 1 has no preexisting claim on banks in other regions, but it can borrow from banks in regions with an excess supply of liquidity. In states like $S_1$ and $S_a$, this mechanism will be enough to achieve the first-best. If the lending rate is $\rho$, then the markets will clear if $1 + \rho = c_2/c_1$. In state $\bar{S}$, however, there will be an economywide shortage of liquidity. The fraction of early consumers is $\gamma + \epsilon$ in region A and $\gamma$ in the other regions; but there is only enough of the short asset in the economy to provide for a fraction $\gamma$ of early consumers. The only way in which more liquidity can be provided to the banks in region A is for the long asset to be liquidated. The other regions will be willing to do this only if the rate of interest on loans compensates for the cost of liquidation: $1 + \rho = R/r$. At this rate, the cost of borrowing is too high to be of any help to the banks in region A. It is just like liquidating more of the long asset, and we have already assumed that the bank is liquidating as much as it can, subject to the incentive constraint.

So the interbank loan market turns out to be of no use in state $\bar{S}$, where there is an economywide shortage of liquidity. It protects other regions from contagion but does nothing to stop the crisis in the affected region.

Although ex post markets allow banks to meet their liquidity needs at date 1, given the first-best choices at date 0, this arrangement is not an equilibrium. If banks expect to be able to borrow and lend at the rate $\rho$, they will not make the first-best choices at date 0. Thus, if the probability of contagion is very small, there will be a welfare loss associated with ex post markets. In richer models, ex post markets to provide liquidity will have problems associated with them. In particular, there can be a lemons problem if banks that have low asset values are more likely to use the ex post loan market than banks that have high asset values. Then it will be difficult for lenders to distinguish between banks that are in trouble because of poor loan performance and banks whose depositors have higher than average liquidity needs. The lemons problem may lead to extremely high interest rates on the ex post interbank market or even to a break-
down of the ex post interbank market. An alternative would be to negotiate a risk-sharing arrangement ex ante, when information is symmetric, and thus avoid the lemons problem altogether.

Another problem with ex post interbank markets arises when lenders have some *monopoly* power. Banks with excess liquidity can exploit banks with insufficient liquidity. Anticipating the possibility of a "holdup," banks will prefer to enter into an ex ante risk-sharing arrangement that fixes the price of liquidity at the risk of contagion.

We have argued that ex post markets can provide liquidity, without risk of contagion, when the uncertainty arises only from liquidity shocks. When uncertainty arises from other sources, however, ex post markets may not be feasible. Consider, for example, the case in which the liquidity shock εᵢ is nonstochastic but the return to the long asset in region i is a random variable Rᵢ. If the returns are not perfectly correlated across regions, there will be gains from sharing risks, and this will lead banks to hold claims on each other. For appropriately specified contracts, the first-best can be achieved through an ex ante interbank market. Ex post, however, there will be no possibility of risk sharing once the values of the random variables \([R_i]\) are known. We chose not to examine this case formally here because of the complexity of the analysis and because the specification of the bankruptcy rules becomes somewhat arbitrary, but it is clear that ex post arrangements will not work in this case. The implications of asset risk are discussed further in Section IX.D.

An interesting question is what kinds of arrangements banks will choose to set up, given the trade-off between the individual benefits of access to liquidity and the social costs of contagion. This is an important topic for further study.

IX. Discussion

A. Equilibrium

In the preceding sections we have discussed the continuation equilibrium at dates 1 and 2 but not said anything about the equilibrium behavior at date 0. It is clear that it is optimal for consumers at date 0 to deposit their endowment with the banks because they could not achieve the same level of expected utility in autarky, even if they were able to invest in both the short and the long assets. What is less obvious is whether the behavior of the banks is optimal in some sense.

The bank has to choose an investment portfolio, a deposit contract, and a position in the interbank deposit market to maximize
the consumers' expected utility at date 0. The tricky part is choosing how much to trade on the interbank market. In order to finance deposits in other regions, it will have to sell its own deposits to other banks. But the value of its deposits will depend on the choice of the investment portfolio and the deposit contract and the withdrawal decisions made by depositors at the second and third dates. We can finesse the complex calculation of the banks' optimal behavior by noting that since all trade is voluntary, anything the bank does to make its own consumers better off cannot make anyone else worse off (since a single bank is negligible, the rest of the economy gets zero surplus from trading with it). Then the fact that the allocation at the second and third dates is first-best optimal implies that there is no deviation that the bank would prefer.

When the probability of a bank crisis is positive, things become much more complicated. The absence of aggregate uncertainty is necessary for the achievement of the first-best. When the probability of a crisis is positive, the first-best is no longer achieved at date 0, and as a result, markets for individual risk sharing are incomplete. As is well known, when markets are incomplete the valuation of assets may vary from individual to individual, there may be a lack of unanimity about the proper objective function for a bank, and the feasible actions for a bank are difficult to characterize.

However, although we have not extended the theory to the more general case, we do not believe that our results are dependent on the assumption that the probability of a crisis is exactly zero. As an illustration, consider the model described in Section V, but make it symmetric by assuming that each of the four regions has an equal probability of being the one with an excess demand for liquidity. The shocks are described in Table 3, where each of the special states $S_\omega, \ldots, S_\delta$ occurs with probability $\delta > 0$ and states $S_1$ and $S_2$ occur with probabilities $\frac{1}{2} - 2\delta$. At date 0 each of the regions is ex ante identical.

Now suppose that risk sharing is to be achieved through a decen-

contralized banking system of the kind described in Section V, but assume that all decisions at date 0 are made by a central planner. The planner will seek to maximize the ex ante expected utility of the representative agent at date 0. He can make any feasible decisions he likes at date 0, but he is constrained to work through the decentralized banking system at dates 1 and 2. In particular, he must use demand deposits to provide risk sharing for individuals and banks. Considerations of continuity imply that when \( \delta \) is small, he must be able to get close to the first-best for the limiting economy with \( \delta = 0 \). If \((c_1^0, c_2^0)\) is the optimal demand deposit and \((x^0, y^0)\) is the optimal portfolio for \( \delta > 0 \), then \((c_1, c_2)\) \(\rightarrow\) \((c_1^0, c_2^0)\) and \((x, y)\) \(\rightarrow\) \((x^0, y^0)\) as \( \delta \rightarrow 0 \), where \((c_1, c_2)\) is the optimal allocation and \((x, y)\) the optimal portfolio from the planner’s problem in Section III. This follows from continuity and the uniqueness of the planner’s optimum. But then the arguments that we have used in Section V imply that in states \( S_\lambda, \ldots, S_\delta \) there must be contagion under the conditions given in Section V when \( \delta \) is sufficiently small. So even if a planner were coordinating the choices made at date 0, there will still be contagion at date 1 in a decentralized banking system.

The reason for this can readily be seen. The way to prevent contagion is to hold a discrete amount more of the liquid asset to meet the extra liquidity demand in states \( S_\lambda, \ldots, S_\delta \). However, holding more of the liquid asset means that less of the illiquid asset is held and output is lower at date 2 in states \( S_1 \) and \( S_2 \). When \( \delta \) is sufficiently small, this trade-off is not worthwhile. It is better to simply allow the possibility of contagion.

The fact that the allocation at the second and third dates is constrained efficient rather than first-best efficient for \( \delta > 0 \) means that decentralized banks may not make even approximately the same choices as the planner at date 0. Such behavior would yield an \( \epsilon \)-Nash equilibrium, but the action profile of an \( \epsilon \)-Nash equilibrium does not have to be close in any sense to the action profile of a Nash equilibrium, however small \( \epsilon \) becomes. Even though everyone would be better off if every bank made the same choices as a planner, they may all find it in their interests (in equilibrium) to behave in a very different way. It may even be true that this date 0 behavior is inconsistent with contagion at date 1; but although this is a theoretical possibility, we cannot think of any reason why it should occur and in fact are quite dubious that it would occur. This is an important topic for future research, but it lies outside the scope of this paper.

B. Many States and Regions

The arguments developed in this paper extend easily to the case of many regions and many states of nature. Suppose that there are \( n \)
regions and suppose that the liquidity shocks $\omega'_{i}$ are finite-valued and exchangeable. If the economywide fraction of early consumers is a constant, then the first-best allocation $(x, y, c_{1}, c_{2})$ is nonstochastic and independent of the consumer's region.

A market structure is characterized by a family of neighborhoods: for each region $i$ the neighborhood $N^{i}$ is the set of regions in which a bank in region $i$ can hold deposits. The market structure is connected if for any regions $i$ and $j$ there is a finite chain of regions, beginning with $i$ and ending with $j$ such that, for each adjacent pair, banks in the first region can hold deposits in the second. As long as the market structure is connected and the maintained assumptions hold, the first-best can be decentralized by a competitive banking sector using standard deposit contracts.

A market structure is complete if banks in region $i$ can hold deposits in every other region $j \neq i$; otherwise it is incomplete. The degree of completeness and connectedness is crucial for determining the inevitability of contagion. When markets are complete, increasing the number of regions eventually eliminates the necessity of contagion for any fixed set of parameter values. The reason is that the initial impact of a liquidity shortage in a single region becomes negligible as the number of regions becomes unboundedly large. In this sense, the banking system is robust against any shock to a single region when the economy is sufficiently large and markets are complete.

On the other hand, when markets are incomplete and the economy is large, small shocks can have extremely large effects. In the example of Section V, a liquidity shortage in one region can lead to crises in all four regions. The same argument works with any number of regions. In fact, as contagion "spreads" from one region to another, the spillovers become larger and it is easier to keep the contagion going. In the general case, contagion can spread from a single region to an arbitrarily large number $n$ of regions.

In this sense, the results for the example of Section V are quite strong and are easily extended to large, complex economies.

C. Sunspot Equilibria

This paper focuses on financial contagion as an essential feature of equilibrium. We do not rely on arguments involving multiple equilibria. The aim is instead to show that under certain conditions every continuation equilibrium at date 1 exhibits financial contagion. Nonetheless, there are multiple equilibria in the model, and if one is so disposed one can use the multiplicity of equilibria to tell a story about financial contagion as a sunspot phenomenon.
To illustrate the multiplicity as simply as possible, suppose that markets are complete and the fraction of early consumers in each region is nonstochastic and equal to $\gamma$. There are no interregional cross holdings of deposits at date 0. If every consumer in every bank chooses to withdraw his deposit at date 1, regardless of the size of the liquidity shock, then the banks will all be bankrupt because $\xi_i > y + rx$. This outcome is an equilibrium because it is optimal for each individual depositor to withdraw assuming that all other depositors withdraw. Of course, there also exists an equilibrium in which late consumers choose not to withdraw until date 2 and the bank’s portfolio $(x, y)$ allows the first-best to be achieved.

The low-probability event $\bar{S}$ is now a “sunspot.” It represents extraneous uncertainty that does not change the demand for liquidity but simply triggers the self-fulfilling prophecy that a bank run will occur. The outcome in terms of the pattern of bank runs in state $\bar{S}$ is the same as in Section V. Whether one wants to call this a contagion is a matter of taste.

D. *Risky Assets*

For simplicity, we have assumed that the long asset has a nonstochastic return, but it would be more realistic to assume that the long asset is risky. In Allen and Gale (1998), the long asset is risky and bank runs are triggered by negative information about future asset returns. In the present framework, uncertainty about long asset returns could be used both to motivate interregional cross holdings of deposits and to provoke insolvency or bankruptcy. The results should be similar. What is crucial for the results is that the financial interconnectedness between the regions takes the form of claims held by banks in one region on banks in another region.

If, instead of holding claims on banks in other regions, banks were to invest directly in the long assets of that region, there would be a spillover effect, but it would be much weaker. To see this, suppose that banks in region A hold some of the long asset in region B. If asset returns are low in region B, then the depositors in region A must accept a reduction in consumption, but that is all. As long as the banks in region A are not bankrupt, they can afford to wait until date 2 to get the higher return $R > r$. Banks in region B, which hold a large proportion of their assets in region B, are forced to liquidate their assets at date 1 and therefore suffer a much greater loss because $r < R$.

On the other hand, if the banks in region A had invested in the banks in region B, then they would suffer a larger loss when the banks in region B liquidate their assets.
Another way in which banks can invest indirectly in risky assets is to lend to investors. If banks cannot observe the investment portfolio chosen by the investors, the investors will engage in risk shifting. Allen and Gale (2000) show that this kind of behavior can lead to bubbles in asset prices and increase the probability of a banking crisis (general default).

E. Alternative Market Structures

Figures 1–3 do not exhaust the possible range of market structures that could exist given the four regions A, B, C, and D. There are two more structures that are substantively different (we ignore the switching of identical regions, such as A for C or B for D). The first alternative is like figure 2, but with regions B and C interchanged. In this case, region A’s and region B’s deposits are made with positively correlated regions rather than with negatively correlated regions as in figure 2. This does not prevent the achievement of the first-best. However, the size of deposits banks must hold in the first-best allocation is doubled. Depending on the state and date, regions will be required to satisfy not only their own liquidity needs but that of the region next to them. In order to do this they must hold twice the deposits they did with figure 2’s market structure, where they had to satisfy only their own region’s shortfall. The higher the level of deposits, the higher the amount of the spillover and hence the more likely there is contagion.

The second remaining market structure is like that in figure 1 but without any deposits in positively correlated regions (i.e., there are no cross links between regions A and C or regions B and D). The first-best can again be achieved. The difference is that in state \( \bar{S} \) the amount of spillover and hence contagion is different. The amount of A’s deposits spread between other regions is smaller than in figure 1 but larger than in figure 2. As a result, the spillover is larger and the contagion more likely than in figure 1; the reverse is true compared to figure 2.

So far we have not mentioned the central bank. The analysis of contagion suggests that one way of thinking about the role of a central bank is to complete markets. In the market structure with a central bank, all banks have a link to it. By intervening appropriately, the central bank can ensure that the inefficient liquidation associated with contagion can be avoided.
